ABSTRACT

Based on Chinese city-level data from 1999 to 2012 and controlling for geological, environmental, and social diversity, our multi-step estimation suggests that credit plays a significant role in driving up house prices after the Great Recession, whereas property prices only influence bank lending before 2008. Local amenities such as higher education, green infrastructure, healthcare, and climate also positively affect house prices. Moreover, the impacts of bank loans on housing prices tend to be related to the level of amenities, suggesting that pooling macroeconomic and urban economic data may be important for housing market research in the future.

1. Introduction

This paper studies the housing market of China and is built on several strands of the literature. First, this paper is related to the debate on whether credit aggregates cause the property market to boom, or the other way round. Although the relationship between credit aggregates and house prices is significantly positive and economically strong in many countries, the direction of causality and the propagation mechanism remain to be resolved empirically. For instance, some studies of the 2006 U.S. real estate market collapse suggest that the subprime mortgage expansion was responsible for bursting the bubble (e.g., Mian & Sufi, 2009; Pavlov & Wachter, 2004, 2006). However, other authors argue that no conclusion concerning causality should be drawn (e.g., Davis & Zhu, 2011; Wheaton & Nechayev, 2008). Similarly, Collins and Senhadji (2002) find evidence for a channel from credit to property price appreciation during the 1997 Asian Financial Crisis. Yet, Gerlach and Peng (2005) claim that property prices in Hong Kong during that period were weakly exogenous, and the causality went from property prices to bank loans, rather than the other way around.

The China's housing market, which has received significant domestic and international attention recently, faces the same set of questions as other markets. According to the data from the CEIC and the National Bureau of Statistics of China (NBSC), the GDP has

grown by a phenomenal rate of 479% between 1999 and 2012, house prices have been up by 200%, but the loan balance has increased tenfold astonishingly. The banking system issued loans worth RMB10 trillion in 2009 alone; this was equivalent to almost one-third of the country's GDP in that year. Together, these figures¹ raise great concerns in business, policy, and academic circles about the sustainability of China's housing market. It is natural to ask whether these housing loans are created by market demand. Or, the bank loans are simply being injected into the economic system by policy decisions? Will China experience a housing market collapse followed by decades of recession, as what happened in Japan? Many researchers have focused on the housing markets at the national or provincial levels.² Although these aggregate-level studies obviously have merits, research at a more disaggregated level would clearly be complementary. For instance, different cities or different regions within the same country may display different patterns, or have different trends in the macroeconomic variables. City-level data not only provide us with a larger sample size, but also are less vulnerable to aggregation bias (Hanushek et al. 1996). Furthermore, the structure of panel data enables us to gain insights on the debate from both the cross-sectional and the temporal dimensions.

Since this study focuses on city-level data, it naturally connects to the second literature, which relates the house price to the local amenities. As housing is a durable and immobile consumption good, location and local amenities matter. Other things being equal, people prefer housing in locations that offer a higher quality of life. Rosen (1979) and Roback (1982) have established that average wages and real estate prices in different places adjust to reflect the values of spatially tied features. Following Rosen and Roback's pioneer work, there have been many studies testing and confirming the existence of compensating differentials in wages and residential property prices in both developed and developing economies (e.g., Berger, Blomquist, & Sabirianova Peter, 2008; Blomquist, Berger, & Hoehn, 1988; Gyourko & Tracy, 1991; Shapiro, 2006). China is large enough to include places characterized by very different climates, environments, and types of social development. The compensating differentials literature contains enlightening research on China, including studies by Zheng and Kahn (2008), Zheng, Fu, and Liu (2009), Zheng, Kahn, and Liu (2010), and Zheng, Cao, and Kahn (2011). Our paper complements previous research by including a broader set of amenities and with a focus of their impacts on housing prices.

Although bank loans and local amenities are seemingly unrelated, we combine analysis of both factors in one research for simple economic reasons. First, it is more than likely that both the credit availability and the geographical distribution of urban amenities have impacts on the city-level demand. And as a matter of fact, loans and some amenity measures may be interacted. While some amenities such as climate may be less influenced by human activities, other amenities such as public health service, or "local fiscal climate" by Gyourko and Tracy (1991), clearly depend on economic activities. Not surprisingly, the second type of amenities and loans can be both tied to the level of economic development, and hence creates some relationships among them. While some previous literature emphasizes how the differences in amenities explain the cross-sectional variations in housing prices, some other literature focuses on how the cyclical movements in bank loans lead to house price fluctuations. Yet in the context of a panel of city-level house prices, as both cross-sectional and temporal components are present, it is not clear a priori which factor will dominate. Integrating these two factors in a simple yet unifying framework should provide a more complete picture of the housing markets.

To achieve the stated objective, it is necessary to select a diverse sample that is also representative of China. Our dataset includes 29 cities; most are provincial capitals that are scattered across the whole country. In addition, most are among the largest cities in their regions, and have a relatively large number of housing transactions. The house price figures are therefore more representative and less likely to suffer from a small sample bias. However, an analysis using simple regression, even with all of the relevant variables included, would still deliver biased estimates, partly due to the multicollinearity among the amenity measures, and partly because the effect of amenities on house prices is also indirectly reflected in income. For instance, both number of doctors and number of hospital beds shared by every 10,000 local population are indicators of healthcare condition; these two measures have a correlation coefficient of 0.78. We tackle the multicollinearity problem by the principal component analysis technique (PCA hereafter). The idea is to reduce various measures to a few variables, and at the same time retain most of the variance in data. In this analysis, 17 amenity measures are consolidated into five categories: climate, air pollution, crime rate, health care, and social development. The formal recognition of the local-amenity differences has important implications for the empirical strategies. For instance, in a city with "better" amenities, these amenities would affect the house prices directly (as people are willing to pay for them), and also affect the house prices indirectly, as an improvement of local amenities may enable the same group of employees to generate more output, as well as attract more capable people to that city and eventually raise the aggregate income of the city.³ Additionally, it seems reasonable to conjecture that with growing income, households would be more willing to pay for certain amenities.⁴ It follows that a two-step procedure is necessary to disentangle the direct and the indirect effects. We first regress income on the principal components of the amenities, and retain the residuals. We label these residuals as filtered income, as they are the part of the income not predicted by local amenities. Then the filtered income is added to the property price regression, together with the normalized loan, the amenities, and the other variables. The natural logarithms of real house prices and real incomes, as well as the normalized loan are further detrended to obtain reliable estimation results. And in order to adjust the within city correlation, clustered standard errors are employed for statistical inference.

Our empirical findings suggest that credit plays a significant role in driving up house prices after the Great Recession, whereas the reversed effect of property prices on bank lending is only present before 2008. More specifically, before the 2008 financial crisis, we find loan volume does not have any significant impact on home prices. However in the post-recession era, such impact is positive and significant at the 5% significance level. If the normalized loan expands by 1%, then the real home prices would be higher by 16.1 basis points next year. In terms of standardized coefficient, an increase of one standard deviation in loan GDP ratio would predict a

¹ These figures are in nominal terms.

² For instance, see Wang and Wen (2012) and the reference therein.

³ Among others, see Davis, Fisher, and Whited (2014) and Wang and Xie (2011) for more discussion on this.

⁴ In other words, the income elasticity of some amenities could be higher than unity.

following 0.179 standard deviations' expansion in real housing prices in the next year. On the other hand, property prices significantly influence bank credit before 2008, but not after. In case of 1% appreciation of real home prices, the bank lending would be greater by 49.3 basis points. In other words, a rise of one standard deviation in house prices would lead to an increase of 0.371 standard deviations in loans in the following year.

Our empirical results also confirm that location is economically very significant. Not surprisingly, people are willing to pay more for housing units located in cities with rich resources in higher education and great green infrastructure. People prefer to live in big cities because of the better economic opportunities, in spite of the crowding and higher crime rates. If the social development component combining higher education, green coverage, and population density has a score greater by one standard deviation, the property prices would be 0.401 standard deviations higher. The amenity indicators capture the location heterogeneity so well that the regional dummies are no longer significant. In an alternative specification, amenity variables such as climate, health care, and social development are found to be significantly and negatively interacted with the normalized loan. It suggests that home prices in cities with more desirable amenities are less sensitive to credit expansion.

The organization of this paper is simple. The next section provides some background on the housing markets, bank loans, and local amenities in China. The literature review is followed by a discussion of the data, and then by a description of the methodology. The results are then presented, and the conclusions are given in the last section.

2. Background on the housing markets, bank loans, and local amenities

For many households throughout the world, a house is not only a shelter, but also the most important investment the household has. Yet for the older generation in mainland China, there was no such thing as private property. Most people lived in apartments assigned by their employers. These arrangements continued until the 1980s when the government launched its housing reform. The administrative housing allocation system was officially abolished in 1998. Since then the government has introduced a series of macro land-use policies to encourage the development of the new private housing market.⁵ Under the joint forces of the private market and government stimulation policies, real estate prices began to increase in 2001,⁶ and then accelerated until 2007. In Fig. 1, we use floor space completed as a proxy for new supply in the real estate market. Floor space sold is intended to stand for demand. When the floor space completed is greater than that sold, the amount of housing unit inventory increases and property prices are kept low. When the new supply does not meet the demand, the amount of inventory in the housing market decreases and the price rises.⁷ At the more disaggregated level, 21 out of the 29 major cities in China had an average housing price growth rate of over 10% annually from 1999 to 2012. An average-sized 120-square-meter apartment in Beijing costs 36 years of disposable income for an average resident in 2004, and by 2012 it costs 52 years of disposable income. Furthermore, as the China Real Estate Index System reported, in 2010 alone the house prices in Beijing surged by 37.1%, and by 47.1% in Hangzhou.⁸

As property prices boomed, so did real estate investments. From 1986 to 2012, nominal investment in China grew at an annual rate of 18%. In contrast, nominal real estate investment expanded at a nearly doubled rate; it grew 32% per year from RMB10 billion to 7180 billion. The proportion of real estate investment over total investment soared from 2.6% in 1986 to 28% in 2012. As investments made up 47.8% of China's GDP, real estate investment accounted for 14% of the total economic activity. Fig. 2 provides a visualization of these observations.

In addition to the frenzied house prices and real estate investments, we also provide a brief review of the monetary policy after 1978. The broad money and outstanding loans increased at an average annual rate of 23% and 19% respectively. Both were faster than the nominal GDP growth which was on average 16%. From Fig. 3, we can see that the proportion of loans issued over GDP has increased to 123% in 2013 from 52% in 1978. The evolving path of the ratio of M2 to output is even more startling. In the late 1970s, M2 accounted for less than 25% of gross production, whereas at the end of the sample period, it was almost 190% of GDP. In 2009 alone, the new loans issued were close to RMB10 trillion, a 33% expansion over the previous year. In 2010, the credit aggregates increased by another RMB8 trillion. The total loan portfolio was expanded by over 50% right after the 2008 financial crisis. Together with the RMB4 trillion stimulus package, these loans were supposed to finance infrastructure projects, but many ended up going to giant the state-owned enterprises where they were used to finance the purchase of real estate instead. According to Wu, Gyourko, and Deng (2012), residential land auctions witnessed land prices doubled in eight major cities in 2009, which in their opinion can be attributed to the massively leveraged purchases by the state owned enterprises (SOEs hereafter). They also show that on average, state-owned corporations pay 27% more than other bidders for the same land parcels. In some ways, the current situation in China's housing market resembles the pre-crisis U.S. property market. The overheated real estate market and the rapid credit expansion have

⁵ For a detailed discussion of these policies, please refer to Leung and Wang (2007) and Zhao, Zhu, and Wang (2008).

⁶ Coastal cities like Hangzhou, Shanghai, and Shenzhen first experienced the rise of housing prices in around 2001 or 2002. Prices in interior cities started to appreciate a little bit later (in around 2003 or 2004).

⁷ Due to the existence of pre-sale of housing units, the comparison between housing completion and housing transaction is probably an imperfect supply–demand indicator. On the other hand, different real estate developments may have different pre-sale periods and to our knowledge, there is no official data which corrects this “pre-sale gap”. In addition, pre-sale means that the ownership of the unit is shifted from the developers to the buyers before the unit is completed. In other words, the existing stock at the time of pre-sale does not increase. The buyers still need to buy or rent other housing units as shelters. It only provides a “hedge” of the house price fluctuations. And there are instances that developers actually go bankrupt after pre-sale and hence are unable to deliver promised units. Being aware of all these limitations, we proceed with this comparison as a proxy.

⁸ Soufun developed the China Real Estate Index System (CREIS) to monitor real estate prices in one hundred cities. For more information, please refer to Anonymous (2011 May 11). The property report: China's tougher mortgage policies. *Wall Street Journal*.

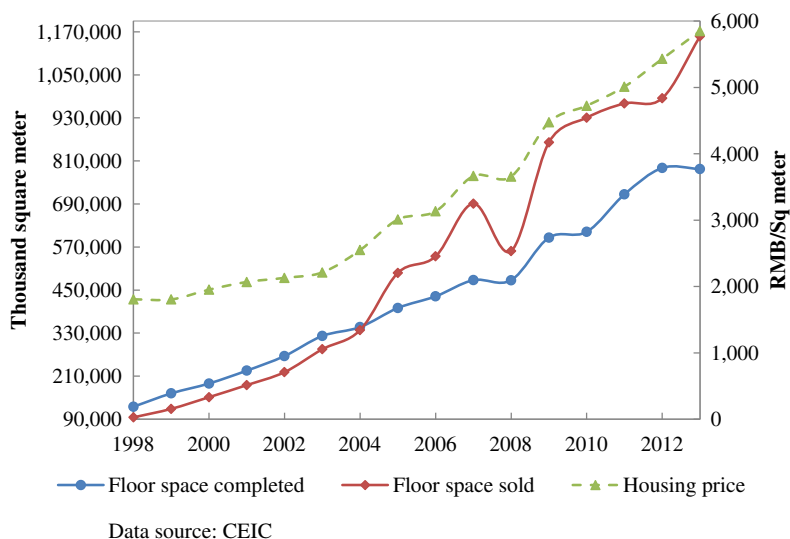

Fig. 1. National housing market.

drawn a lot of attention, as the affordability of housing is of great concern to the general public, and the bursting of a real estate bubble could cause serious problems for the banking system and the macroeconomy.

China has achieved great economic success since its economic reform and opening up. But it has always been a great country with huge cross-sectional variations in amenities. According to the Encyclopedia Britannica, China is the third largest country by area. It stretches from the Russian border in the north, to the South China Sea. In the west, it extends into the Pamir Mountains, the “roof of the world”. The landscape is vast and diverse and the climatic and geological environments vary from region to region. Thus, it may be interesting to investigate how the local housing markets behave given such geographical diversity. Our sample of 29 large cities, most of them provincial capitals, is highly representative for such diversity. For example, our sample includes Kunming, the “city of eternal spring” in the south-western Yunnan province,⁹ and the “ice city” of Harbin, located in the north-eastern Heilongjiang province, which has the coldest and longest winter in China. Temperatures in Kunming range from 31.3 °C (88.3 °F) in the summer to −4 °C (24.8 °F) in the winter, while the lowest recorded temperature in Harbin is −37.3 °C (−35.1 °F) in the same period. The geology not only shapes the diversified climate, but also affects the “colors” seen in satellite photos. Western China is covered by deserts, mountains, and plateaus, and has an arid climate. In contrast, the east, consisting of the Northeast Plain, the North China Plain and the Middle–Lower Yangtze Plain, is characterized by humid warm weather. Correspondingly, the green coverage ratio is higher in the east than in the west. The average urban green coverage ratio is over 36% in eastern cities in our sample, whereas this figure is only 29% in the western cities.

These broad climatic and geological environments are reflected in large cross-sectional variations in the cities. The availability of higher education also varies dramatically across regions. In 1995, the central government launched an initiative called “Project 211” to promote China’s higher education by providing funding to universities. So far, only 112 of the 2358 universities and colleges in the country are enrolled in the program.¹⁰ Therefore, a designation as a 211 Project institution is an indicator of educational quality. The number of universities sponsored by the Project in a city may be a proxy for cultural richness, higher education quality, or even the human capital environment. The distribution of these universities is uneven across the country, with 26 in Beijing, ten in Shanghai, eight in Nanjing, seven in Wuhan, and seven in Xi’an. In total, these five cities are home to half of the best universities and colleges in the nation; there is only one such institution in most other major cities, and none in Ningbo and Shijiazhuang.

The same pattern can be seen in the distributions of the health workforce and facilities. There are 3.6 and 3.4 doctors per 1000 people in Guangzhou and Beijing respectively, which is comparable to the standards in European countries such as Germany, France, and Denmark.¹¹ In contrast, the doctors’ density in Chongqing and Shijiazhuang is only 1.4 and 1.8, respectively. The density of hospital sickbeds is also high in Beijing and Guangzhou and low in Chongqing and Shijiazhuang. In Guangzhou, there are 5.7 sickbeds serving every 1000 people. The figure is 4.8 in Beijing. But 1000 people have to share 2.4 sickbeds in Chongqing, and 3 in Shijiazhuang.

Air pollution also varies significantly across cities. The World Health Organization (WHO hereafter) issued in 2011 a database¹² recording outdoor air pollution in 91 countries and 1100 cities. According to this database, 20 among the top 100 most polluted cities are in China. In particular, Beijing ranked the fifth within the country and fiftieth world-wide. In fact, according to the state-run Xinhua

⁹ There is a special article in the December 8, 2012 issue of iMoney magazine called “New favorite mainland city of Hong Kong capital, Kunming” (in Chinese). It gives a very detailed description of Kunming’s climate and geography, and how these features are going to attract Hong Kong capital. In that article, Kunming is compared to the warm and beautiful Florida.

¹⁰ There are more and more colleges and universities in China nowadays, but the 211 Project probably will not expand any more.

¹¹ The worldwide data are available on the WHO website http://www.who.int/gho/health_workforce/physicians_density/en/index.html.

¹² The full dataset can be downloaded from http://www.who.int/phe/health_topics/outdoorair/databases/en/.

Fig. 2. Ratio of real estate investment over total investment.

news agency and the air quality daily report¹³ by the Beijing Municipal Environmental Protection Bureau, Beijing's air pollution hit dangerous levels on ten days in January 2013, and on one day, the $PM_{2.5}$ ¹⁴ reading was 993 μg per cubic meter. Although air pollution is challenging sustainable growth everywhere in China, the south remains in relatively better condition. In the WHO database, the top five polluted cities, including Lanzhou, Xining, Urumqi, Jinan, and Beijing, are all in the north, and the least polluted five cities,¹⁵ Haikou, Nanning, Fuzhou, Kunming, and Guangzhou, are all in the south. As the Chinese grow rich, so are their marginal valuations on quality of life. The three large-scale local protests¹⁶ in 2012 against environment-harming industrial projects are convincing evidence of people's willingness to pay for desirable amenities.

3. Literature review

Changes in the real estate and credit markets can be mutually reinforcing. House price appreciation can cause credit expansion. As illustrated by Kiyotaki and Moore (1997) and other authors, as both households and firms use property as collateral for borrowing, the net worth of households' collateralizable assets increases with house prices. Such change in net worth enables them to borrow even more. From the banks' point of view, real estate values affect their capital positions. In good times, the loans secured by real estate collateral are even safer, and the banks' direct holdings of property assets also appreciate. This perception increases financial institutions' risk-taking capacity and their willingness to extend credit, so they pour more loans into the economy. Supporting empirical research of such a cause and effect link from house prices to credit volume includes studies by Leung (2004), Gerlach and Peng (2005) and Peng, Tam, and Yiu (2008).¹⁷ Gerlach and Peng (2005) study the housing market of Hong Kong in the 1982 to 2001 period. Their co-integration analysis suggests that the property prices in Hong Kong are weakly exogenous, and the causality goes from property prices to bank loans. Peng et al. (2008) investigate the relationship between the property market and the macroeconomy in mainland China from 1998 to 2004, using panel data covering 25 provinces and six major cities. Their results show a two-way linkage between property price inflation and GDP growth. Furthermore, property price growth has a positive and significant effect on investment, especially real estate investment, but not on consumption. Thus, the causal relationship also seems to go from property price appreciation to credit expansion.

As the supply of housing stock is typically inelastic in the short run, an increase in bank credit may drive up house prices. Studies supporting this hypothesis include Mian and Sufi (2009), Collins and Senhadji (2002), and Coleman, LaCour-Little, and Vandell (2008). Mian and Sufi (2009) conduct a within-county analysis using detailed zip code-level data from 1991 to 2007. They find that mortgage credit grows unprecedentedly in subprime zip codes despite the relative income growth declines. Moreover, the negative relationship between mortgage credit and income is still significant in Metropolitan Statistical Areas (MSAs) with elastic housing supplies, implying that the subprime lending expansion is not due to lenders' expectations of higher future house prices. The authors suggest that the relative house price appreciation in subprime communities is the result of the increase in credit supply. Collins and Senhadji (2002) report strong relations between credit growth and asset price booms in Indonesia, Malaysia, Philippines, South Korea, Thailand, Hong Kong, and Singapore. Using panel regressions and individual country VARs, the authors also argue for a credit channel to property price appreciation. Coleman et al. (2008) run a pooled cross-sectional analysis of 20 MSAs in the 1998–2006 period to

¹³ The data are available on this webpage: <http://www.bjepb.gov.cn/air2008/Air.aspx?time=2013-1-28>. Historical data can be obtained by modifying the enquiry date.

¹⁴ $PM_{2.5}$ measures the number of tiny particles with diameters less than 2.5 μm . Such particulate matters can enter deep into human lungs and cause potential cardiovascular and respiratory diseases. The recommended standard for $PM_{2.5}$ in the U.S. is below 35.4 μg per cubic meter. If the measure rises beyond 210.5, the air quality is rated as hazardous.

¹⁵ Lhasa in Tibet, the Hong Kong Special Administration Region, the Macau Special Administration Region, and cities in Taiwan are excluded.

¹⁶ Two of the three protests occurred in July 2012, one in the eastern coastal city Qidong in Jiangsu Province, and one in Shifang in the south-western Sichuan Province. The third protest happened in October 2012, and was also in the eastern coastal city Ningbo.

¹⁷ Among others, see Chen and Wang (2007) for loan-level evidence and more discussion of this point.

Fig. 3. Ratios of broad money and loans over GDP.

investigate housing price dynamics. In the earlier years of their sample, economic fundamentals such as unemployment, population, income, and capital cost are found to be the primary driving forces of the house price dynamics. However, they lose significance towards the end of the observation period. The authors also discover that Government-Sponsored Enterprises (GSEs hereafter) are the main supplier of mortgage capital prior to 2004, whereas from late 2003 GSEs are squeezed out of the market by private issuers who wildly increase subprime lending. All of these studies suggest that credit expansion is the main driving force of house price appreciation, especially in the recent years.

Other studies find mixed evidence regarding the direction of causality. For instance, [Wheaton and Nechayev \(2008\)](#) use time series techniques to examine whether the appreciation of house prices between 1998 and 2005 can be explained by economic fundamentals. They estimate a single-stage univariate model for each of 59 U.S. MSAs from the 1970s to 1998, and then use actual economic data from 1998 to 2005 to forecast house prices. They find large magnitude of errors in the forecast. However, the explosive growth in credit availability brought about by the subprime lending, as well as the purchase of the second and investment home, predict the forecast error significantly.¹⁸

In addition to the literature on the link between house prices and bank credit, there is another strand of research in urban economics, compensating differentials, that is relevant to our study. [Rosen \(1979\)](#) and [Roback \(1982\)](#) lay down the basic framework for this line of research. They argue that people compete for amenable places to live, but as wages and home prices are adjusted to reflect spatially tied amenities, people have no incentive to move from one location to another. They set up a simple general equilibrium model to derive the comparative statics of wages and real estate prices. They also employ the hedonic pricing variant to test the hypothesis empirically. They find that housing prices are higher in cities with better amenities. However, the same is not necessarily true of wages. In their studies, pollution, extreme climate, and crime are documented as dis-amenities, and mild weather and, surprisingly, population density as desirable amenities. They construct a quality of life index using the implicit price estimates.

Building on Rosen and Roback's pioneer work, [Blomquist et al. \(1988\)](#) modify their model by including more than one county in each urban area to account for agglomeration effects. With a large cross-sectional dataset of 253 counties in 185 U.S. metropolitan areas, they derive new measures of quality of life, which reveal substantial variations both within and among urban areas. Their list of amenity variables is more extensive than that used in earlier research; it includes teacher–student ratio, violent crime rates, and even climate and environmental attributes. [Gyourko and Tracy \(1991\)](#) re-estimate the compensating differentials using the same census data as [Blomquist et al. \(1988\)](#). Although they shift the focus to central cities of metropolitan areas and work with an even longer amenities list including police, fire, health, education services, and local tax rates, their estimates of the characteristic variables, especially the pure amenities like climate, almost always bear the same signs as in [Blomquist et al. \(1988\)](#). Additionally, their study indicates that public safety, and fire and health services have a statistically significant effect on local wages. More recently, [Shapiro \(2006\)](#) demonstrates that human capital, as an indicator of local amenity, also has a causal effect on wages, rents, and house prices. But the author suggests that the influence on rents and home values is much larger than that on wages.¹⁹

The hypothesis that the concern for quality of life may rise with income, has inspired a growing number of studies on the compensating differentials in emerging markets. For example, [Berger et al. \(2008\)](#) apply the Rosen–Roback framework to Russian labor and housing markets. Their results are consistent with those found in developed countries, and confirm the applicability of the Rosen–Roback framework to transition economies. In addition to the traditional amenities such as climate, environment, crime rates, and health services, they also find that ethnic conflicts matter in Russia.

When it comes to the research on China's housing market, there have been many interesting studies as well. [Leung and Wang \(2007\)](#) apply the DiPasquale–Wheaton model to China and conduct policy analyses. [Leung, Chow, Yiu, and Tam \(2011\)](#) propose

¹⁸ In a cross-country study, [Davis and Zhu \(2011\)](#) also find a two-way relationship between bank lending and commercial property price using panel error correction model.

¹⁹ Among others, see also [Albouy \(2009\)](#), [Albouy et al. \(2013\)](#), and [Glaeser \(2008\)](#).

simple models for house price and construction dynamics, and estimate model implications with data from four major cities. Shen (2012) develops a new housing affordability measure in terms of permanent income, and argues that housing affordability in China is fairly strong according to their new measure. Ren, Xiong, and Yuan (2012) test the existence of rational expectation bubbles. Wang, Yang, and Liu (2011) inspect how economic openness affects real estate prices. Liang and Cao (2007), Liang and Gao (2007), Peng et al. (2008), and Zhang, Gong, and Bu (2006) contribute to the topic of interaction between bank lending and property market. However, these articles carry out their investigation at the national or provincial level. City-level research in this field has been rare due to data limitations. Deng, Morck, Wu, and Yeung (2011) suggest a channel through which credit is poured into real estate investment by SOEs using land auction data from eight major cities. Their paper focuses on the land markets. With a manually collected dataset, we attempt to complement to the analysis of the relationship between bank loans and house prices from the disaggregated city level.

Efforts have also been made to estimate compensating differentials in the context of China, including Zheng and Kahn (2008), Zheng et al. (2009), Zheng et al. (2010), Zheng et al. (2011), among others. Building on the same Rosen–Roback framework, Zheng and Kahn (2008) use two micro-datasets of land sales and project-wide house prices in Beijing to estimate the capitalization effects of local public goods. The authors find proximity to public transit, parks, core high schools, and universities all have significantly positive effects, and air pollution has a significantly negative impact on prices. Following Zheng and Kahn's (2008) early work on Beijing, Zheng et al. (2009) extend the research to 85 Chinese cities. Using China's Urban Household Survey, the authors perform a similar hedonic analysis of the amenity premium in 1998 and in 2004. This study incorporates more amenity variables than Zheng and Kahn (2008), such as climate and healthcare. The findings indicate a strong increase between 1998 and 2004 in urban resident's willingness to pay for amenities. Another study of compensating differentials by Zheng et al. (2010) uses cross-city panel data from the 1997 to 2006 period. They document that green space and air pollution have significant effects on house prices, but in opposite directions. In contrast to Shapiro (2006), they find the effect of their measure of human capital insignificant. The effect of climate is also insignificant. Zheng et al. (2010) contribute to environmental economics by establishing that FDI inflows reduce pollution levels. Zheng et al. (2011) put even more weight on environmental economics; they study both air pollution production and its capitalization effect on real estate prices. The same 85 cities as in Zheng et al. (2009) in the 2006 to 2008 period are sampled, but an IV strategy is adopted to address the endogeneity of pollution. The authors find air quality and hospital beds have significant effects on house prices, but climate and teacher–student ratio do not.

Building on these authors' insights, this paper attempts to complement the literature by examining how a wide range of amenities are reflected in property prices, even after bank loans and other control variables are taken into account. Zheng and Kahn (2008) focus their analysis on Beijing. Zheng et al. (2010) and Zheng et al. (2011) concentrate on environmental issues. Zheng et al. (2009) mainly concern the compensating differentials in wages and housing rents. In addition, previous studies incorporate at most five aspects of amenities or disamenities. For each aspect, only one measure is adopted. The indicators of air pollution in these studies may serve as an illustration. Zheng et al. (2009) select sulphur dioxide emissions only, while in Zheng et al. (2010) and Zheng et al. (2011), the authors use particulate matter concentrations. However, both sulphur dioxide and particulate matter are important pollutants. Restricting their choice to either one means loss of information. Such practice is probably due to the concern that if more measures of the same amenity are included, estimation will be complicated by high collinearity among the measures (Ridker & Henning, 1967). With the help of principal component analysis, we are able to mitigate the multicollinearity problem and include multiple measures for every amenity. In total, we incorporate 17 measures covering seven aspects of amenities or disamenities in this article: climate, air pollution, crime rate, health care, urban crowding, higher education, and green infrastructure, the last three of which are consolidated into one principal component.

4. Data

While previous studies on China's real estate market are interesting and inspiring, there are rooms for further improvement. First, they adopt the provincial level data in their research, which may combine information from both urban and rural areas. Their measure of real estate prices mixes residential, commercial, and industrial real estates. In addition, the composition and the relative importance of different types of real estates may vary across cities. Thus, a more disaggregated dataset with a price series exclusively focused on residential sector would provide more insights into China's municipal housing markets. In light of these considerations, we collect annual data for the 1999–2012 period for 35 major cities representing all the provinces in China except Tibet, the Hong Kong Special Administration Region, the Macau Special Administration Region, and Taiwan. Six cities including Haikou, Hohhot, Nanning, Shenzhen, Xining, and Yinchuan are excluded due to missing variables and data reliability problems. There is at least one city in the sample for most provinces, and for areas such as Liaoning, Fujian, Zhejiang, and Shandong province, there are two cities allowing for further analyses. These cities are scattered throughout China, and demonstrate large cross-sectional variations. Together, they represent China's geological, environmental, and social diversity.

The variables we collect can be divided into two groups. One group contains house prices, loans issued by the financial institutions of each city, per capita²⁰ disposable income, long-term interest rates, and stock market returns. As all of these variables are nominal, we convert them into real ones using city-level CPI and inflation rate.²¹ The second group is variables for location-

²⁰ Variables involving population, such as per capita disposable income and population density, are calculated based on the population with "Hukou". The authors try to collect data on total population from municipal statistical yearbooks. But some cities choose to report total population, while others still report officially registered population only. The lack of consistency makes our efforts fruitless.

²¹ There is currently no city-wide or province-wide fixed based CPI. We obtain the December CPI of each city with previous year as base from CEIC. City-level inflation rate is generated by CPI minus 100. Assuming the 1999 CPI equals to 100 for every city, we add the inflation rate back to derive an alternative CPI series.

ties. Specifically, we include local population density, the number of 211 Project universities in each city, green coverage ratio of each city, number of doctors and hospital sickbeds shared by every 10,000 people, number of suspects arrested or prosecuted by the local procuratorate every 10,000 people, the amount of yearly sunshine and precipitation, extreme temperatures, relative humidity, and the concentrations of PM₁₀, SO₂, and NO₂ in the air. As the data come from various sources, we provide detailed variable descriptions and data sources in [Appendix A](#). The descriptive statistics reported in [Table 1](#) give an overview of how these variables evolve during the sampling period.

It is clear from [Table 1](#) that real house prices, real bank loans, and real per capita disposable income all increased enormously as the economy developed.²² Average real property prices and real per capita disposable income almost tripled. The real loans volume experienced a fivefold increase. Housing prices grew the fastest in Ningbo,²³ a beautiful coastal city in Zhejiang province, at an average growth rate of 13.6% throughout the sample period. Shenyang²⁴ witnessed the slowest average growth rate, 4.9%, in the same period. The growth rates in real bank lendings were much larger, around 15% in most cities in our sample. The fastest growth was in Changsha, Hefei, Ningbo, and Taiyuan, each of which had a rate of over 20%. The growth rates in real income were similar to that of the house prices, but with smaller variances. Income in most cities grew at around 10%. The income in Urumqi grew at the slowest pace (5.7% annually). To avoid scale effect, we normalize loan volume by GDP. And since it is highly likely that there exist long-run trends in these three series, we detrend these series in conjunction with deflating and logging.

For our amenity variables, we consider seven aspects: urban crowding, higher education, crime rates, health care, green space coverage, air pollution, and climate. Following the literature and considering data availability, we use per square kilometer population density to measure urban crowding, and green coverage ratio to represent local green infrastructure. The data collection methods for healthcare resources, air pollution, and climate are consistent with previous research, but we include more dimensions to capture more information. As we discussed earlier, the previous literature has examined the effects of particulate matter and sulphur dioxide. We include both pollutants, and add nitrogen dioxide²⁵ due to its adverse health effects on human respiratory systems. For the same reason, we include the number of doctors and hospital sickbeds per 10,000 people as measures of the municipal healthcare resources. Our measures of climate include extreme temperatures, temperature difference,²⁶ amount of annual sunshine and precipitation, and relative humidity. Unfortunately, there is no crime data at the city level, so we use the number of suspects arrested and prosecuted by the local procuratorate per 10,000 population in each province as a proxy. These raw measures of air pollution, health care, climate, and crime rate are first treated with principal component analysis before entering the regression. The method will be discussed in detail in the next section.

While class size or student–teacher ratios in elementary schools are often used as measures of educational resources, we use the number of 211 Project universities by population in the municipality instead. There are at least three reasons for such a substitution. First, the locations of these universities are arguably more exogenous than other variables such as the average student–teacher ratio or class size. These universities were established a long time ago, and are not the product of recent economic developments.²⁷ Second, the variations are larger in tertiary education than in primary and secondary education. There are 26 universities in Beijing that are funded by “Project 211”, ten in Shanghai, eight in Nanjing, seven in Wuhan, seven in Xi’an, one in most other major cities, and none in Ningbo and Shijiazhuang. And finally, living around a key higher education institution means beneficial exposure to well-educated peers and easy access to university campus where large open space, sports facilities, and libraries are available. In fact, [Zheng and Kahn \(2008\)](#) have demonstrated that proximity to major universities is a desirable feature for home-buyers, whereas the insignificance of student–teacher ratios is documented by [Zheng et al. \(2011\)](#).

Our panel dataset might have an additional merit. Some previous studies on the relationship between amenities and house prices focus on the cross-sectional differences. While these cross-sectional differences are clearly important, it might overlook the fact that local amenities do change over time. For instance, the health care provision in many cities improves over the sample period, especially in Changsha, Chengdu, Guangzhou, Hangzhou, and Jinan. Some places have cleaner air (e.g., Chongqing, Kunming, and Nanjing, Wuhan) in the sense that the pollutant emissions are reduced as time passes by. At the same time, public security has been deteriorating in all cities. One possible explanation is that the growing income gap between the rich and the poor drives up the expected benefit of committing a crime. We provide a visualization of the increase of hospital beds in our sampled cities from 1999 to 2012 in [Fig. 4](#). [Appendix C](#) reserves more details about the temporal change in amenities for interested readers. These “stylized facts” further reinforce the view that amenities would change with income and therefore it is important to adopt a unifying framework including both amenities and bank loans to study the house prices in different cities.

²² Note that in China, most bank loans are made by the four major, state-owned banks. Thus, the total bank loans are a sum of the loans made by private banks and state-owned banks. Our regional dataset, however, does not provide us with the information necessary to differentiate the two. See [Geiger \(2006\)](#) for more discussion of this problem.

²³ Zhejiang is one of the most advanced eastern provinces in China. Ningbo is the second most famous city in this province, and its importance is only second to the provincial capital, Hangzhou.

²⁴ Shenyang is the provincial capital of the north-eastern Liaoning province, which is economically less developed than Zhejiang province.

²⁵ The health effects of nitrogen dioxide can be found on the website of the United States Environmental Protection Agency: <http://www.epa.gov/oaqps001/nitrogenoxides/health.html>.

²⁶ The temperature difference is defined as (maximum temperature – minimum temperature)² / 100.

²⁷ In fact, it is well-known that increasing teachers' salaries or reducing student–teacher ratios do not necessarily lead to “better” education outcome. See [Hanushek \(2006, 2009\)](#). In addition, [Hanushek and Yilmaz \(2007\)](#) analyze household mobility when school qualities differ across communities.

Table 1
Summary statistics.

Variables	1999		2012	
	Mean	Standard deviation	Mean	Standard deviation
Real house price (Yuan per square meter)	2016.286	946.322	5862.114	2976.219
Real loan (billion Yuan)	114.010	110.813	732.930	622.461
Loan GDP ratio (proportion)	1.422	0.689	1.696	0.534
Real income (Yuan per capita)	7310.339	2894.575	21,156.735	5717.690
Real long-term interest (%)	7.986	1.566	3.969	0.418
Real stock market return (proportion)	0.192	0.017	0.024	0.004
Real fixed asset investment (billion Yuan)	29.675	36.369	262.895	161.467
Fixed asset investment over GDP (proportion)	0.332	0.128	0.659	0.219
City-level inflation rate (%)	−1.076	1.430	2.711	0.412
Maximum temperature (°C)	36.181	2.341	36.291	2.933
Minimum temperature (°C)	−9.924	8.504	−10.118	10.882
Yearly sunshine (hours)	1958.747	570.851	1914.536	598.991
Yearly precipitation (millimeter)	945.494	574.347	982.347	557.980
Relative humidity (%)	67.294	10.507	65.933	11.608
PM ₁₀ (micrograms per cubic meter)			88.686	23.178
SO ₂ (micrograms per cubic meter)	69.818	56.316	35.171	14.496
NO ₂ (micrograms per cubic meter)			40.600	9.829
Days with good air quality			330.824	24.749
Number of suspects arrested per 10,000 population	5.867	2.008	7.629	2.976
Number of suspects prosecuted per 10,000 population	6.132	2.357	11.193	4.212
Number of doctors per 10,000 population	27.884	10.317	34.354	16.909
Number of hospital beds per 10,000 population	43.035	15.477	58.913	15.576
Population density (persons per square kilometer)	624.338	477.825	736.278	641.709
Number of project 211 universities	3.029	4.662	3.029	4.662
Green space coverage (%)	31.057	7.860	40.034	4.554

Notes:

1. Long-term interest rate is the benchmark interest rate for loans with maturities of five years or longer specified by the People's Bank of China. Real long-term interest rate takes the city-level inflation into account.
2. Days with good air quality is the number of days with air quality of Grade II or above in the whole year according to the criteria given by the Ministry of Environmental Protection of China.
3. "Project 211" is an initiative launched by the central government in 1995 to promote China's higher education. A designation of a 211 Project university is an indicator of educational quality.
4. Table A1 provides a complete list of variable definitions and data sources.

5. Empirical framework

5.1. Principal component analysis (PCA)

A typical challenge for empirical research on local amenities is that we either do not include enough measures of the amenities, or we do have many measures and yet multicollinearity exists among them, which makes the econometric results a bit difficult to interpret. For example, indicators for climate, such as the amount of precipitation and relative humidity, are naturally highly correlated. The same is true for other amenities. Such multicollinearity has been documented by [Ridker and Henning \(1967\)](#). When all of our amenity measures are included in the regression analysis, most of them are insignificant and display counterintuitive signs. Simply dropping some will result in the loss of valuable information. To mitigate the multicollinearity problem while preserving the information in the data, we use principal component analysis,²⁸ a popular statistical method that reduces the data dimensionality and at the same time retains as much variance as possible.

The PCA recommends preserving five principal components out of 17 raw measures. These five components jointly account for over 70% of the total variance. Each component can be thought of as a weighted sum of the standardized amenity variables with scoring coefficients in [Table 2](#) as weights. Since most weights are assigned to minimum temperature, temperature difference, sunshine, and humidity, we can roughly regard component 1 as climate indicator. By the same token, component 2 measures air pollution, component 3 stands for crime rate, and component 4 represents local healthcare condition. Each component proxies one kind of amenity except the last one, which mixes urban crowding, higher education, and local green infrastructure together. We term component 5 social development.

²⁸ Principal component analysis and related methods have been used widely in previous studies. See [Jolliffe \(2005\)](#) for a review of the literature on this subject.

Fig. 4. Boxplot of Chinese cities' hospital sickbeds.

Notes:

1. The data of the number of hospital beds are from China City Statistical Yearbook. The authors calculate the density of the hospital beds among every 10,000 population using population data from China City Statistical Yearbook and China Statistical Yearbook.
2. The lower hinge of each box represents the 25th percentile, the upper hinge represents the 75th percentile, and the line within each box indicates the median. Outside values are excluded.

5.2. Two-step regression analysis

Although PCA is adopted to mitigate the multicollinearity problem, a simple regression with PCA-consolidated variables may still fail to give accurate estimates of the effects of local amenities, as those amenities may affect house prices directly as well as indirectly by changing the local income. To have a better understanding of the mechanism through which amenities affect the house price, our regression analysis is conducted in two steps. First, we regress the log transformed and detrended real incomes on local amenities and retain the residual. The residual could be interpreted as the “filtered income”, i.e. the income that is not predicted by local amenities. We put this residual term together with other explanatory variables into the second-step regression to get more consistent estimates of income and amenity variables.

Step 1:

$$Income_{i,t} = b_0 + X_{i,t}b + e \quad (1)$$

Income is the log transformed and detrended real per capita incomes. *X* is the row vector of five principal components including climate, air pollution, crime rate, health care, and social development. Although some of these amenities may not be strictly exogenous, they can be considered as predetermined (Keane & Runkle, 1992). The amenity level, such as health care provision, is the result of past fiscal policies, and is presumably independent of future income shocks. According to Greene (2012), predetermined variables can be treated “as if they were exogenous in the sense that consistent estimates can be obtained when they appear as regressors.”²⁹ We calculate the residual from the regression (the part of income unexplained by amenities) and denote it as the filtered income. The subscript *i* is an index for city, *t* for year.

Step 2:

$$House\ Price_{i,t} = \beta_0 + \beta_1 Loan_{i,t-1} + \beta_2 Filtered\ Income_{i,t} + \beta_3 Interest\ Rate_{i,t} + \beta_4 Stock\ Market\ Return_{i,t} + X_{i,t}\beta_5 + \varepsilon \quad (2)$$

House Price is the log transformed and detrended real housing prices. *Loan* is the detrended loan GDP ratio. *Filtered Income* is the residual from the first-step regression. *Interest Rate* is the real long-term borrowing rate, and serves as the proxy for mortgage rate. *Stock Market Return* is the current-value-weighted aggregated market returns with cash dividend reinvested. It is included since the stock market return may reflect the market sentiment or represent the future productivity growth.³⁰ *X* is the same row vector of amenities as in the first step. In order to tackle the cross-sectional heterogeneity in Chinese cities, we also include the regional dummies. Each city is placed in one of the four categories, i.e., northeast, east, west, and central China, according to the division criterion of the NBSC. A similar practice has been adopted by other authors.

²⁹ We will show in Section 6.3 that endogeneity in these produced amenities may not be a serious issue in the current sample. For more discussion on endogeneity issue in econometrics, see Angrist and Pischke (2010), Sims (2010), among others.

³⁰ See Greenwood and Jovanovic (1999) and Hobbijn and Jovanovic (2001) for more discussion.

Table 2
Matrix of scoring coefficients.

Raw measures	Comp1	Comp2	Comp3	Comp4	Comp5
Maximum temperature (°C)	0.156	0.214	0.116	−0.242	0.214
Minimum temperature (°C)	0.472	−0.012	−0.007	0.043	0.036
Temperature difference	−0.456	0.052	0.045	−0.090	−0.001
Yearly sunshine (hours)	−0.455	−0.081	−0.008	0.124	0.110
Yearly precipitation (millimeter)	0.319	−0.056	0.003	0.079	0.086
Relative humidity (%)	0.433	−0.030	−0.055	−0.015	−0.046
PM ₁₀ (micrograms per cubic meter)	−0.076	0.491	−0.119	−0.004	0.061
SO ₂ (micrograms per cubic meter)	0.078	0.478	−0.003	0.095	−0.253
NO ₂ (micrograms per cubic meter)	0.037	0.321	0.366	0.020	0.057
Days with good air quality	0.025	−0.528	0.083	−0.015	−0.078
Number of suspects arrested per 10,000 population	0.029	−0.042	0.613	0.052	−0.046
Number of suspects prosecuted per 10,000 population	−0.067	−0.072	0.637	−0.018	−0.020
Number of doctors per 10,000 population	0.037	−0.039	0.014	0.671	0.032
Number of hospital beds per 10,000 population	−0.024	0.085	0.017	0.664	0.007
Population density (persons per square kilometer)	0.133	0.081	0.189	−0.047	0.405
Number of project 211 universities per 10,000 population	−0.092	0.142	−0.037	0.016	0.603
Green space coverage (%)	0.029	−0.217	−0.085	0.065	0.569
Cumulative proportion of variance	0.227	0.393	0.526	0.637	0.723

Notes:

1. The temperature difference is (maximum temperature − minimum temperature)² / 100.
2. Days with good air quality is the number of days with air quality of Grade II or above in the whole year according to the criteria given by the Ministry of Environmental Protection of China.
3. “Project 211” is an initiative launched by the central government in 1995 to promote China’s higher education. A designation of a 211 Project university is an indicator of educational quality.
4. Table A1 provides a complete list of variable definitions and data sources.

For the purpose of alleviating the endogeneity problem, we include the one-year-lagged instead of contemporary *Loan* in the second-step regression. Limited by the sample size, we can afford to consider one lag only. In order to justify our approach of combining bank loans and local amenities in one framework, we conduct model comparison by carrying out three housing price regressions, all with log transformed and detrended real house prices as dependent variable. The first regression includes macroeconomic variables as regressors. The second regression includes urban amenities as controls. And the third regression integrates both, the specification of which is provided in Eq. (2). The goodness-of-fit statistics of the three empirical models are summarized in Table 3. Compared with the first two columns, the third has the highest adjusted R-squared and F-statistic, the lowest AIC, BIC, and root mean squared error (RMSE). And as will be shown by the same regression on standardized variables in column (2) of Table 4, apart from the lag term of bank credit, urban amenities also have larger standardized coefficients than some macroeconomic variables, which means amenities have relatively greater impacts on detrended real house prices than filtered income, long-term interest rate, and stock market return. Together with the significant interaction between loans and amenities to be reported in Table 7, these evidence suggest that the specification in Eq. (2) is a better empirical model.

Since housing prices within the same city tend to be correlated over the years, it is prudent to use clustered standard error to deal with the possible intra-class correlation. On the other hand, clustering analysis tends to inflate the standard errors even more than heteroskedasticity robust standard errors. The statistical significance of the point estimates is expected to be affected.

5.3. The reversed effect of house prices on loans

To inspect the effect of house prices on credit, we run the loan regressions.³¹ Following Peng et al. (2008), fixed asset investment is included to capture the investment demand for bank credit. The stock market return is taken into account for two reasons. During a hot stock market, on the one hand, as households draw deposit from banks to invest in the stock market, the banks will have to reduce the loan supply. On the other hand, firms also turn to the stock market as an alternative financing source. Both reasons suggest that the loan volume may be negatively related to the stock market return. We fit the loan equation with a fixed effect model.

$$\begin{aligned} \text{Loan}_{i,t} = & \gamma_0 + \gamma_1 \text{House Price}_{i,t-1} + \gamma_2 \text{Income}_{i,t} + \gamma_3 \text{Fixed Asset Investment}_{i,t} \\ & + \gamma_4 \text{Interest Rate}_{i,t} + \gamma_5 \text{Stock Market Return}_{i,t} + \mu \end{aligned} \quad (3)$$

Fixed Asset Investment refers to the annual fixed asset investment over GDP ratio. Other variables carry the same definition as in Eqs. (1) and (2). Contemporary *House Price* is replaced by its one-period lag to address the endogeneity concern.

³¹ In this regression, income enters the right hand side without filtering.

Table 3
Empirical model comparison.

	(1) Macroeconomic Variables	(2) Local Amenities	(3) Both
n	223	223	223
k	7	8	12
Adjusted R-squared	0.80	0.79	0.85
RMSE	0.18	0.19	0.16
F	28.41	41.12	69.65
AIC	−116.17	−104.27	−166.74
BIC	−88.91	−73.61	−122.45

Notes: Please refer to Section 4 for the list of the macroeconomic variables and the local amenities. The data sources are provided in Table A1.

6. Empirical results

6.1. Main results

As previously discussed in Section 5.2, we fit three empirical models for housing prices to facilitate model comparison. The findings from the full model which combines bank loans and urban amenities in one unifying framework will be discussed in detail in this section. Results of the other two models are reserved in Appendix B. To justify our use of the PCA technique, we perform a regression with the raw amenity measures and provide the results in Appendix B as well. Regression output with PCA-consolidated amenity variables and unfiltered income can also be found in Appendix B.

Our discussions begin with the outcome of the second-step regression with PCA technique applied on the full sample from 1999 to 2012. Column (1) of Table 4 reports the point estimates and their associated p-values. Column (2) documents the corresponding standardized coefficients. Since standardized coefficients inherit the same statistical significance as point estimates, we omit the p-values and significance stars in column (2). In the full-sample outcome, the elasticity of the house prices with respect to the detrended and filtered real income is 1.017, which indicates the detrended real housing prices would be 1.017% higher if the income increases by 1%. In terms of standardized coefficient, real property prices will rise by 0.324 standard deviations if the income goes up by one standard deviation. Such effect is statistically discernible from zero at the 1% significance level. The coefficient of real stock market return on real house price is around 0.021, which is statistically significant at the 1% significance level. This confirms previous findings that the stock market and housing market tend to co-move.³² However, the coefficient estimate of the normalized loan is not significantly different from zero, detailed discussion of which will be provided in the subsample analysis. The long-term interest rate is not significant either.

Column (1) of Table 4 also shows that estimates for crime rate and the principal component representing higher education, green space coverage, as well as urban crowding are highly significant at the 1% significance level. All amenities except crime rate display the anticipated signs. A comparison with Table B4 confirms our conjecture that income is not completely exogenous. Cities with more desirable amenities would attract people with higher abilities and incomes. Statistically speaking, we need to adopt a 2-stage procedure to address such “implicit selection”. Notice that the point estimates are elasticities of house prices with respect to the corresponding component score. The interpretation should be how a one-score change in the principal component would influence the property prices. For example, an improvement of one score in the social development component would push house prices up by 12.8%. One standardized deviation increase in the social development indicator would result in 0.401 standardized deviations appreciation in the housing prices. Recall the social development component is made up of higher education, green infrastructure, and urban crowding. Our findings are consistent with existing evidence. The premium for green infrastructure has been previously documented by Zheng et al. (2009) and Zheng et al. (2010), while similar positive influence of education or human capital can be found in Blomquist et al. (1988), Gyourko and Tracy (1991), and Zheng et al. (2009). Our paper is closest to Zheng and Kahn (2008) in the sense that both inspect the impact of higher education. Conventionally, a higher population density implies crowding and should suppress house prices. However, recent studies suggest that a more concentrated population may be associated with better learning and matching in the labor market (Bleakley & Lin, 2012; Laing, Palivos, & Wang, 1995), better matching in the marriage market (Gautier, Svarer, & Teulings, 2010), more product variety (Schiff, 2012), etc. Thus, a higher population density can have a positive effect on house prices. In fact, Roback (1982) also documents a significantly positive influence of population density on residential site prices. We believe the same reasoning applies to public security. Great and economically successful cities usually also breed more crime. The positive capitalization effect of crime is also reported by Blomquist et al. (1988), Gyourko and Tracy (1991), and Berger et al. (2008). The amenity variables capture the location heterogeneity well so that regional dummies are no longer significant.

Running regression on standardized variables, we directly compare coefficients to assess the relative strengths of the corresponding variables in explaining the variance in housing prices. In column (2), one-year lag of normalized credit has a standardized coefficient of 0.094, and real income 0.324. Among all the explanatory variables, the long-term interest rate has the smallest standardized coefficient, −0.008, which means one standard deviation increase in the interest rate almost does not alter the property prices. All the amenity components have greater standardized coefficients than the mortgage rate proxy do. The standardized coefficients of social

³² Among others, see Leung (2007) on the relationship between the stock market and the housing market in equilibrium.

F	69.65		41.20		59.95	

Notes:

1. Clustered standard errors are computed to draw inference. P-values are in brackets. The stars *, **, and *** indicate the significance level at 10%, 5%, and 1% respectively.
2. House price is measured in terms of Yuan per square meter. The measurement unit of income is Yuan per capita. These two variables are first deflated, then transformed into natural logs, and finally detrended. Loan GDP ratio is detrended as well. Income is further filtered by urban amenities.
3. Long-term interest rate is the benchmark interest rate for loans with maturities of five years or longer. We subtract city-level inflation rate from nominal long-term interest rate, and nominal stock market return to obtain the corresponding real values. Long-term interest rate is in percentage, while stock market return is in proportion.
4. Climate, air pollution, crime rate, health care, and social development are all principal components obtained from the principal component analysis. The first four components stand for what their names suggest. Social development is more composite and captures population density, green space coverage, as well as higher education.
5. Coefficients for regional dummies are suppressed to save space.
6. Please refer to Table A1 for a description of the data sources.

development and crime rate are even larger than those of bank lending and income. Clearly such comparison is possible only when both bank loans and urban amenities are included in a unifying framework.

To investigate how housing prices may influence loans, we fit Eq. (3) to data using fixed effect method and report the estimation results in column (1) of Table 5. As the column shows, home price lag significantly and positively affects loan GDP ratio. The point estimate is 0.53, and the standardized coefficient is 0.414. In plain language, 1% appreciation in the property price would induce the future credit volume to expand by 53 basis points, while one standard deviation increase in the property price would correspond to 0.414 standard deviation increase in bank lending in the following year. The impact of the normalized fixed asset investment is larger in elasticity, but smaller in terms of standardized coefficient. If the fixed asset investment over GDP ratio is higher by 1%, the demand for bank loans would be almost 1% greater. If the fixed asset investment goes up by one standard deviation, the credit would grow by 0.356 standard deviations. The first instinct about interest rate, a measure of borrowing cost, is that higher interest rate should suppress borrowing. However, a more careful reasoning casts doubt on this simple intuition. Interest rate is an endogenous variable. When there is huge demand for capital, the borrowing cost will naturally climb up. And when the economy “overheats”, the central bank will also raise the interest rate to cool it down. As a result, we observe a positive relationship between the interest rate and the credit.³³ Our negative estimate of the real stock market return is evidence of our conjecture that stock is another investment vehicle to households, and the stock market is an alternative financing source to firms. Despite being statistically insignificant, the estimate for detrended real income is of a negative sign, which echoes the finding of Peng et al. (2008). Cities with higher income tend to have more diversified financing channels and rely less on bank loans.

³³ It may take a more structural model to investigate the relationship between interest rate and property market formally and hence we leave this for future research.

Table 5

6.2. Subsample analysis

As is shown in Figs. 1 and 3, both house prices and loans have gone through several different stages. It is therefore natural to wonder whether our results derived from the full sample also hold in different sub-samples. In this section, we will discuss our findings for subsamples.

Due to the limitation of sample size, we can only afford to divide the whole sample into two subsamples, which are Before the Great Recession, and after. A further attempt to break the pre-crisis subsample into before and after 2003 will result in too few observations for the period prior to 2003. As our sample begins in 1999, the first subsample (i.e. Before the Great Recession) has more observations than the second one. In fact, both the qualitative and quantitative results for the period between 1999 and 2008 are very similar to those in the full sample. Therefore, we will put more effort into documenting the findings for the post-recession era.

In the housing price regression for the data after 2008 reported in columns (5) and (6) of Table 4, we find that bank credit plays a significant role in driving up home prices, which is consistent with Liang and Cao (2007), and Liang and Gao (2007). Furthermore, the magnitudes of both point estimate and standardized coefficient are larger compared to the results in the other columns of Table 4. To be more specific, if the loan GDP ratio goes up by 1%, the house prices in the following year would appreciate by 16.1 basis points. And one standard deviation increase in the current financial institutional lending would lead to a 0.179 standard deviations growth in the real house price in the next year, with everything else held constant. In contrast, the coefficient on the real income changes in the opposite direction. Both the coefficient values and the statistical significance decline. The influence of the stock market return becomes insignificant as well. We believe such failure of precise estimation is caused by the small amount of identifying variance (Griliches & Mairesse, 1995) in the stock market return from 2009 to 2012. The other variables have the same pattern as documented in the last section.

In sum, we find the bank lending has contributed to the property price inflation in a time of easy credit, but not before. Nevertheless, the pattern of statistical significance is reversed in the case of how the real estate prices have influenced the loan volume. From 1999 to 2008, our estimate suggests that the housing prices significantly and positively affected the loan GDP ratio, rather than the other way around. Peng et al. (2008) reached the same conclusion for the period from 1998 to 2004. In the second sub-sample, the impact from the previous year real house price on bank loan switches from significant to insignificant. Even income does not appear to have any power in explaining loans after the Great Recession. Again probably because of the reduced amount of variations in the interest rate and stock market return, their estimates lose significance as well in the second subsample. The only statistically significant variable is the normalized fixed asset investment. In spite of this, the adjusted R-squared surprisingly jumps to 0.97 in column (5). Putting the small sample issue aside, the results here are in fact consistent with a recent literature, which suggests that the “stimulus package” implemented by the Chinese government after the Great Recession, which tends to focus on fixed asset investment, may play a key role in explaining the bank loans in China.³⁴

³⁴ Clearly, it is beyond the scope of this paper to survey this growing literature on the impact of the post-crisis response of China. Among others, see Csanadi, Nie, and Li (2013), Garcia-Herrero and Santabarbara (2011), IMF (2014), and Wong (2011).

6.3. Endogenous amenities

This section shifts the attention to amenities. Obviously, some amenities are completely exogenous such as climate, while others are not. Urban crowding, green infrastructure, public health care, crime rate, and air pollution are produced by human society (Blomquist et al., 1988; Gyourko & Tracy, 1991; Roback, 1982; Rosen, 1979), and may not be strictly exogenous. Thus, to examine the effect of amenities on the house prices, one needs to address such endogeneity concern. In this section, we conduct the same two-step analysis on amenities as we do on income. Notice that our amenity variables are linear combinations of all raw amenity measures, and thus there is measurement error in them when they are viewed as indicators of amenities. For example, component 1 is mostly about climate, but it also contains other information, and cannot be thought of purely exogenous. We therefore apply the filtering process to every component. We regress the produced amenities against detrended real income and retain the residuals as “filtered” amenities in the first step, which are then inserted into the second-step regression together with the other variables specified in Eq. (2).

Overall, our findings are not weakened by this “cleaning procedure” applied to the amenity variables. Regarding how the bank loans have affected the housing prices, the results remain the same as in Table 4. The empirical results on how amenities affect house prices actually become sharper. Due to such similarities, we focus our discussion on the post-recession estimation reported in columns (5) and (6) of Table 6. After removing the “endogenous component of amenities”, the effect of income on home prices is much greater. If one city is richer than another by 1% of filtered income, it would also have the house prices higher by 3.792%. Such a huge effect is not unlikely if housing is considered as a “luxurious good” by the households. Then an increase in income would lead to a higher proportion of expenditure share on housing in the total budget. Since the housing supply is quasi-fixed in the short run, an increase in the expenditure share will be translated into a higher housing price at the equilibrium. Among the amenities, social development and crime rate are still highly significant. Now, other amenity components also become significant. The standardized coefficient of the climate component is 0.369, which is larger than that of the normalized loan and almost four times of the previous estimate for climate in Table 4.

Notice that such an important impact of climate we have obtained is different from what Zheng et al. (2010) and Zheng et al. (2011) have found. These two studies documented a negligible climate effect. The difference of the results may be due to the measurement issue. These studies measure climate by a function of temperatures, while this paper includes a more inclusive measure through

Long-term interest rate is in percentage, while stock market return is in proportion.
4. Climate, air pollution, crime rate, health care, and social development are all principal components filtered by income. The first four components stand for what their names suggest. Social development is more composite and captures population density, green space coverage, as well as higher education.
5. Coefficients for regional dummies are suppressed to save space.
6. Please refer to Table A1 for a description of the data sources.

the principal component method. Thus, our result may suggest that *other aspects of climate* such as sunshine, precipitation, and relative humidity matter for the housing market. In addition to climate, the healthcare component has become marginally significant as well. The associated standardized coefficient has also grown from 0.018 in Table 4 to 0.078 in Table 6, an over three times' increase. This finding about the importance of local healthcare condition is consistent with existing literature. Zheng et al. (2009) show that people are willing to pay a positive rental premium for more doctors in town. Zheng et al. (2011) have documented the number of sickbeds in hospitals and clinics positively affect newly-built house prices.

6.4. Interaction effects

We have argued that loans and some amenities may interact with each other through their relations to a common third variable. In this section, this thesis is examined more formally. More specifically, we incorporate the interactive terms of loans and other variables

Table 7

Notes:

1. Clustered standard errors are computed to draw inference. P-values are in brackets. The stars *, **, and *** indicate the significance level at 10%, 5%, and 1% respectively.
2. House price is measured in terms of Yuan per square meter. The measurement unit of income is Yuan per capita. These two variables are first deflated, then transformed into natural logs, and finally detrended. Loan GDP ratio is detrended as well. Income is further filtered by urban amenities.
3. Long-term interest rate is the benchmark interest rate for loans with maturities of five years or longer. We subtract city-level inflation rate from nominal long-term interest rate, and nominal stock market return to obtain the corresponding real values. Long-term interest rate is in percentage, while stock market return is in proportion.
4. Climate, air pollution, crime rate, health care, and social development are all principal components obtained from the principal component analysis. The first four components stand for what their names suggest. Social development is more composite and captures population density, green space coverage, as well as higher education.
5. Constant and coefficients for regional dummies are suppressed to save space.
6. Please refer to Table A1 for a description of the data sources.

in the estimation. The new regression becomes

$$\begin{aligned} \text{House Price}_{i,t} = & \beta_0 + \beta_1 \text{Loan}_{i,t-1} + \beta_2 \text{Filtered Income}_{i,t} + \beta_3 \text{Interest Rate}_{i,t} + \beta_4 \text{Stock Market Return}_{i,t} + X_{i,t} \beta_5 \\ & + \text{Loan}_{i,t-1} X_{i,t} \beta_6 + \varepsilon. \end{aligned} \quad (4)$$

Overall, this regression supports the position that credit and amenities are indeed inter-related. Here are more details. Compared with Table 6, the goodness of fit improves in Table 7. The estimate for the loan GDP ratio gains significance even in the full sample. The amenity variables remain as significant as in Table 6. More importantly, the interaction effects between climate, health care, crime rate and bank lending are statistically significant, with signs in line with our expectation. The multiple of social development and bank lending is almost significant as well. Notice that bringing in interactive terms in the regression demands more cautions in the interpretation of the results. Here are our interpretations. The influence of credit on housing prices now varies across the level of amenity. The negative coefficients on the interactive terms suggest that home prices are less sensitive to credit expansion in cities with better amenities such as more pleasant climate, more green space coverage, better health care and higher education. In addition to the full-sample results, we also briefly review the subsample findings. From 1999 to 2008, the main effect of the normalized loan is statistically indistinguishable from zero, the same as the overall effect in column (3) of Table 6. Though the main effects of amenities are very similar to their full-sample counterparts in column (1) of Table 7, the interactive terms seem to become more important in the econometric model. In fact, after 2008, only the interactive term of pollution and loan ratio is significant. The statistical significance of other interactive terms could be “reduced” due to the small sample issue. We can only wait for future research to confirm this speculation.

6.5. Panel estimation

To further exploit our dataset which has both cross-sectional and temporal variations, we perform additional panel data estimation. Consistent with our previous results, the impact of credit on house price is found to be significant only after the Great Recession. Therefore, to save space, we limit our discussion to the post-recession results in this section. The fixed effect model has the advantage of allowing the unobserved individual effects to be correlated with the covariates. The tradeoff is “using the most restricted amount of variance for the identification of the various coefficients” (Griliches & Mairesse, 1995). In our case, we run the Hausman test to determine whether random effect or fixed effect model should be adopted. The Hausman test does not reject the consistency of the random effect model for the data after 2008. We present the results from the fixed effect model as well.³⁵

The first two columns of Table 8 report the fixed effect and random effect estimations of Eq. (2), corresponding to the last two columns of Table 4. The two columns in the middle of Table 8 are the panel estimation counterparts of columns (5) and (6) in Table 6. And the last two columns of Table 8 can be compared to those in Table 7. After a comprehensive comparison, we find the random effect estimates of the lagged normalized loan are very close to previous ones. Although the within transformation reduces the amount of variance in data, the coefficient on the loan variable is still significant in column (5) of Table 8, and is marginally significant in columns (1) and (3). However, the same parameter is slightly bigger in the fixed effect model than in the random effect model. When it comes to the real income, the random effect estimates are greater than the ordinary least squares estimates. The fixed effect estimates of income are quite different across the three specifications. Unlike previous regressions, the coefficients of interest rate become statistically significant, and carry stable values using either the fixed effect or the random effect estimator. The negative sign further suggests that interest rate has an impact on the housing price. Among the amenity variables, both the significance pattern and the magnitude of the significant estimates are similar to those in Tables 4, 6, and 7. The interaction effects are more significant in the full sample, just the same as the case in Table 7.

7. Conclusions

As the world economy struggles to move out of the recession, the Chinese economy can no longer depend on the driving force of exports to prevent it from slowing down. In fact, some developed countries are expecting to export their goods and service to China. If the Chinese real estate market crashes at this time, China and many of her trading partners would suffer serious setbacks; this scenario is of great concern to both researchers and the general public.³⁶ Most of the existing research on the relationship between credit expansion and house price surge relies on aggregate data at the provincial or national level, leaving out the issues caused by geographical heterogeneity. This study uses a unique, hand-collected city-level dataset to take the first step in assessing the interactions among bank loans, property prices and local amenities. Since both credit and amenities influence house prices, and since the effects of these two factors are interacted, we combine them in one simple yet unified framework. And our model has the capability to evaluate the relative importance of different factors.

To conclude our findings, the housing prices had significantly affected the financial institutional lending before the Great Recession, whereas after the crisis the loan expansion has been an important force driving up the home prices. When the real property prices went up by 1% before 2008, the loan GDP ratio would be greater by almost 50 basis points in the next year according to our estimate. If instead the house prices experienced an increase of one standard deviation, the future normalized loan would expand by 0.371 standard

³⁵ As we present the earlier version of this paper in different conferences, there are audiences interested in the findings from the fixed effect model. For a more engaging discussion of the fixed effect model and the random effect model, see Hsiao (2003).

³⁶ See The Economist Magazine (2013) for a special report on this topic.

Table 8

Post-recession housing price panel regression.

Dependent variable: log(real house price)	Main Specification		Endogenous Amenities		Interaction Effects

Number of cities	29	29	29	29	29	29
F	1.859		1.859		17.14	

Notes:

1. Clustered standard errors are computed to draw inference. P-values are in brackets. The stars *, **, and *** indicate the significance level at 10%, 5%, and 1% respectively.
2. House price is measured in terms of Yuan per square meter. The measurement unit of income is Yuan per capita. These two variables are first deflated, then transformed into natural logs, and finally detrended. Loan GDP ratio is detrended as well. Income is further filtered by urban amenities.
3. Long-term interest rate is the benchmark interest rate for loans with maturities of five years or longer. We subtract city-level inflation rate from nominal long-term interest rate, and nominal stock market return to obtain the corresponding real values. Long-term interest rate is in percentage, while stock market return is in proportion.
4. Climate, air pollution, crime rate, health care, and social development are all principal components. The first four stand for what their names suggest. Social development is more composite and captures population density, green space coverage, as well as higher education.
5. Constant is suppressed to save space.
6. Please refer to Table A1 for a description of the data sources.

deviations. On the other hand, in the post-recession era, 1% incremental change in the loan ratio would boost the real property prices by 16.1 basis points in the following year. In terms of standardized coefficient, an increase of one standard deviation in the loan ratio would lead to a growth of 0.179 standard deviations in the future house prices. Such empirical results imply that although the loans were once truly demanded by the market, they begin to influence the asset prices when an enormous amount of them are poured into the economy. Besides bank lending, local amenities such as climate, health care, higher education, and green space coverage are also capitalized into house prices. And the amenities' impacts are by no means weaker than that of the credit. For example, the standardized coefficients of climate and social development (the composite component of population density, higher education, and green infrastructure) are 0.357 and 0.71 respectively. Both are greater than that of the bank lending, which is 0.179. Comparing our results with the literature also suggests that "climate" is more than temperature. Sunshine, precipitation, and relative humidity all matter for the housing market. The healthcare indicator has a standardized coefficient of 0.075, also larger than that of the interest rate (0.06) and the stock market return (-0.057). Last but not the least, the credit and some amenities including climate, crime rate, health care, and social development are negatively interacted with each other, suggesting that property prices are less sensitive to lending growth in cities with more desirable amenities.

The evidence we have documented is likely to carry important policy implications. First, monetary policy is important for the house price stability as it would impact the credit expansion. This is especially important for China as all major banks are

national, and hence the Chinese government can implement the monetary policy in ways different from many other countries. Second, the local government investment in amenities can lead to increase in house prices. One possible reason for why amenities affect property prices is that cities offering high quality of life can attract immigrants, whose living needs push up housing demand much more than the supply is able to adjust. Apart from contributing to home price, the influx of new labor, especially the high quality human capital, is beneficial for promoting productivity of the city as well (Peri, 2012). On the other hand, amenities via housing demand can influence local land sale revenue, which in the current context of China is an important determinant of local government financial position.

One limitation of our study is there may be concern for external validity. The current sample covers only relatively developed cities in China with more active financial markets. The link between the bank credit and the housing market may be stronger in these cities. As urbanization is still an undergoing process for China, meaning that small and medium cities of today could become big cities in the future. Understanding the housing market, urban amenities, and government policy could be very important. Thus, this study may also shed light on those emerging cities. In addition, the China experience may shed light for other developing countries as well.³⁷

Clearly, our analysis is far from being the last word on this issue. Household-level data and the mortgage loan data, when become available, should be used to confirm our tentative conclusion. Since there has been evidence of improved regional capital mobility in China as the economy develops (Chan, Dang, Lai, & Yan, 2011), future research could also investigate whether there exists spatial spillover among regional housing markets, and what role does regional capital flow play in such spillover effect.

Acknowledgments

The authors would like to thank Belton Fleisher, Pohan Fong, Xu Han, Vikas Kakkar, Kamhon Kan, Jennifer Lai, Huimin Li, Mi Lin, Chung Yi Tse, Yi Wen, Isabel Yan, Zan Yang and the participants at the 2013 ASSA-CEANA Meeting, the Seventh Biennial Conference of the Hong Kong Economic Association, the 2012 AsRES-AREUEA International Conference, the GCREC 2012 Annual Conference, WEA conference (2013), and at the City University Brown Bag seminar, and especially anonymous referees for their comments. In addition, we are grateful to City University of Hong Kong for its financial support. The work described in this paper was partially supported by a grant from the Research Grants Council, University Grants Committee, Hong Kong [project no. CityU 144709]. Part of the research is done when Leung visits ISER, Osaka University, whose hospitality is gratefully acknowledged. The usual disclaimers apply.

Appendix A. Supplementary data

This appendix provides some supplementary materials to the main text. Appendix A is a complete list of variables used in our analysis. In Appendix B, there are four housing price regressions, including one with the macroeconomic variables only, one with the PCA-consolidated amenities only, one with the 17 raw amenity measures, and one single-step regression with consolidated amenity components and unfiltered income. And several graphs in Appendix C are to show that amenities are not constant but vary over time. Supplementary data to this article can be found online at <http://dx.doi.org/10.1016/j.chieco.2015.03.002>.
